ABSTRACT

We report the discovery of optical and radio afterglow emission from the extremely soft X-ray flash, XRF 020903. Our spectroscopic observations provide the first redshift for an X-ray flash, thereby setting the distance scale for these events. At $z = 0.251$, XRF 020903 is one of the nearest cosmic explosions ever detected, second only to the recent GRB 030329 and the unusual GRB 980425/SN 1998bw. Moreover, XRF 020903 is the first X-ray flash for which we detect an optical afterglow. The luminosity of the radio afterglow of XRF 020903 is 1000 times greater than that of Ibc supernovae but similar to those of GRB afterglows. From broadband afterglow modeling we show that the explosion energy of XRF 020903 is not dissimilar from values inferred for typical gamma-ray bursts, suggesting that these cosmological explosions may derive from a similar mechanism.

Subject headings: gamma-ray bursts: specific (XRF 020903)—supernovae: general

1. Introduction

Prior to the detection of afterglows, gamma-ray bursts (GRBs) were enshrouded in mystery for nearly thirty years. Great progress in our understanding of these energetic events came with the first redshift measurement which placed GRBs at cosmological distances (Metzger *et al.* 1997). In a similar fashion, the mystery of X-ray flashes (XRFs) has been fueled by the absence of confirmed redshifts. These events, identified in the 1990s by *BeppoSAX*, are characterized by a peak energy in νF_ν of $E_{\text{peak}} \sim 25$ keV (compared to $E_{\text{peak}} \sim 250$ keV for GRBs). With a distribution of durations similar to those observed for GRBs, it has been assumed that XRFs are associated with GRBs and therefore share their extragalactic distance scale (Heise *et al.* 2001).

The subsequent discovery of XRF X-ray and radio afterglows with properties similar to those observed in GRB afterglows has further strengthened this association (Harrison *et al.* 2001; Amati *et al.* 2002; Taylor, Frail & Kulkarni 2001). Still, the question of whether the difference between GRBs and XRFs is intrinsic or extrinsic remains unanswered. Assuming XRFs are simply GRBs observed away from the jet collimation axis, they would have less γ -ray emission and the difference is extrinsic, based solely on the line-of-sight to the observer. On the other hand, the difference could be intrinsic, namely XRFs may represent a class of explosions which are similar in energetics to GRBs yet characterized by less relativistic ejecta possibly due to a heavier baryonic load. It is clear that by setting the distance scale for XRFs (and hence their energy scale) we can begin to distinguish between extrinsic and intrinsic effects.

In this paper we present the first spectroscopic redshift for an X-ray flash, XRF 020903, placing this event among the nearest high energy explosions and offering confirmation that X-ray flashes are cosmological and produce a total energy output similar to that observed in GRBs.

2. Observations

On 2002 September 3.421 UT the Wide-Field X-ray Monitor (WXM) and Soft X-ray Camera (SXC) aboard the High Energy Transient Explorer-2 (HETE-2) detected an X-ray flash within the 0.5-10 keV energy band. With an exceptionally low peak energy of $E_{\text{peak}} \sim 5$ keV and a fluence of 7.2×10^{-8} erg cm $^{-2}$, XRF 020903 is the softest event ever detected by HETE-2 with a ratio of X-ray fluence (S_X) to γ -ray fluence (S_γ) of $\log(S_X/S_\gamma) = 4.3$ (Sakamoto *et al.* 2003). Ground analysis provided a localization for XRF 020903 centered at $\alpha(\text{J2000}) = 22^{\text{h}}49^{\text{m}}01^{\text{s}}$, $\delta(\text{J2000}) = -20^\circ55'47''$ with a $4' \times 31'$ uncertainty region at $\Delta t \approx 0.3$

days (Ricker *et al.* 2002).

2.1. Ground-based Photometry

We began observing the field of XRF 020903 on 2002 September 4.32 UT ($\Delta t \approx 0.9$ days) with the Palomar Observatory 200-inch telescope (P200) equipped with the Large Field Camera (LFC). With a total exposure time of 20 minutes under photometric conditions (stellar FWHM $\sim 1.2''$) the observations reached a limiting magnitude of $R \sim 23$ mag. Visual comparison with Digitized Sky Survey archival images did not reveal an afterglow candidate.

A second epoch was obtained on September 10.30 UT ($\Delta t \approx 7$ days) using the same observational set-up and in similar observing conditions. Image subtraction between the first and second epochs revealed one variable object within the HETE-2 error region (Figure 1) located at $\alpha(\text{J2000}) = 22^{\text{h}}48^{\text{m}}42.34^{\text{s}}$, $\delta(\text{J2000}) = 20^{\circ}46'09.3''$ and lying ~ 4 arcsec NW of a bright elliptical galaxy (hereafter G2; Soderberg *et al.* 2002).

With an approximate magnitude of $R \approx 19$ at $\Delta t \approx 1$ day, the new object decreased in brightness by 1.4 magnitudes between the two epochs, implying a temporal flux decay index of $\alpha \approx -1$. As the source proved consistent with a typical GRB afterglow evolution, the optical transient was adopted as a suitable candidate for the optical afterglow of XRF 020903.

We observed the afterglow position on three additional epochs with the P200 and the MDM Observatory 1.3 meter telescope (Table 1 and Figure 2). These, along with Digitized Sky Survey archival images, reveal the presence of an extended source with $R \sim 21$ mag coincident with the position of the transient and thereby suggestive of a host galaxy (hereafter G1).

Due to the underlying extended source and the proximity of the transient to G2, accurate magnitude estimates relied on careful PSF photometry of the field. Absolute calibration of field stars was supplied by Henden (2002). We used 12 unsaturated field stars in common between the Palomar and Henden images to fully calibrate observations of the variable source. We note that although the transient decreased in brightness quickly between the first two epochs, later epochs ($\Delta t \approx 30 - 40$ days) appear to indicate a plateau in the light curve which was confirmed by other observers (Gorosabel *et al.* 2002) and may originate from unresolved flux contamination from G1.

2.2. Ground-based Spectroscopy

Initial spectroscopy of the transient was performed on 2002 September 28.1 UT with the Magellan Baade Telescope using the Low Dispersion Survey Spectrograph (LDSS2). A position angle of 168 degrees was used such that spectral information on G1 and G2 was obtained simultaneously. Despite the positional coincidence of G2 and G1, it was found that the systems are not physically associated, separated by 3900 km/s in velocity space (Soderberg *et al.* 2002). In this epoch, the transient source was still significantly bright.

Further spectroscopic observations were made of the putative host (G1) with the Echelle Spectrograph & Imager (ESI) mounted on the Keck II telescope on 2003 July 4 UT ($\Delta t \approx 300$ days). These observations do not include any flux from the transient source. During a total exposure time of 1 hour, we obtained a spectrum of G1 and G2 with a slit width of 0.75 arcsec.

We find that G2 is a large elliptical galaxy with at least one interacting galaxy companion, G3, located $< 1''$ to the NE (see Figure 4). Observations of G2 exhibit a relatively smooth continuum with features typical of an elliptical galaxy. The Ca II H and K absorption lines give a redshift of $z = 0.235$, while G3 is offset by only 240 km/s at a redshift of $z = 0.236$.

In contrast, G1 is shown to be an active star-forming galaxy at $z=0.251$ with a rich set of narrow bright emission lines (Figure 2). The [OIII]/H β and [NII]/H α intensity ratios indicate that the galaxy is a low-metallicity and high-excitation starburst galaxy. In addition, the flux ratio of the [NeIII] and [OII] lines is $F^{3869}/F^{3727} \approx 0.43$, similar to the observed value for the host galaxy of GRB 970508 (Bloom *et al.* 1998) and approximately 10 times higher than typical values for H II regions. The bright [NeIII] emission lines observed in GRB hosts are thought to be indicative of a substantial population of massive stars. On the other hand, Chornock & Filippenko (2002) note that a spectrum of G1 taken with the Low Resolution Imaging Spectrometer (LRIS) on the Keck I telescope reveals a deficit of emission at rest wavelengths $< 4000\text{\AA}$ which is consistent with a population of older stars.

2.3. Hubble Space Telescope

The afterglow candidate was observed with the Hubble Space Telescope (HST) using the Advanced Camera for Surveys (ACS) under Program No.9405 (P.I.: A. Fruchter). Three epochs of imaging were obtained from $\Delta t \sim 94$ to ~ 300 days with exposure times of 1840 sec in the F606W filter. Following “On-The-Fly” pre-processing the data were drizzled using standard IRAF tools (STSDAS; Fruchter & Hook 2002). In drizzling our final images, we

retained the native WFC pixel scale of $0.05''$ and used a `pixfrac` of 1.0. The HST images reveal a complex galaxy morphology for G1, suggesting a system of at least four interacting galaxies (see Figure 4).

To locate the optical transient with respect to the host galaxy complex, we performed a source to source comparison of our first-epoch Palomar (2002 September 4) and HST (2002 December 3) images. We found 42 unsaturated, unconfused sources in common between these two images, and were able to match the two coordinate lists with an rms mapping uncertainty of 0.06 arcsec. We derived the position of the transient from the difference image of the 2002 September 4 and September 10 data. Since the optical transient is well-detected in the difference image, the uncertainty in its centroid position is negligible. The uncertainty in the coordinate mapping thus dominates the uncertainty in the position of the source relative to the host galaxy complex. The optical transient appears to overlap with the SW component of the G1 complex (Figure 4).

2.4. Radio Observations of XRF 020903

2.4.1. Very Large Array Data

We began observations of the field of XRF 020903 with the Very Large Array (VLA¹) on 2002 September 27.22 UT. A radio source was detected in coincidence with the optical transient at a location of $\alpha(\text{J2000}) = 22^{\text{h}}48^{\text{m}}42.34^{\text{s}}$, $\delta(\text{J2000}) = -20^{\circ}46'08.9''$ with an uncertainty of 0.1 arcsec in each coordinate. The initial observation showed the radio source to have a flux density of $F_{\nu} = 1.06 \pm 0.02$ mJy at 8.5 GHz. The National Radio Astronomy Observatory VLA Sky Survey (NVSS; Condon *et al.* 1998) did not show any evidence for a pre-existing source at this location down to a limit of 1 mJy. Further observations at 8.5 GHz on September 29.11 ($\Delta t \approx 26$ days) showed that the source faded to $F_{\nu} = 0.75 \pm 0.04$ mJy. We continued monitoring the transient source with the VLA over the next ≈ 370 days at frequencies of 1.5 , 4.9 , 8.5 and 22.5 GHz. The lightcurve is displayed in Figure 5.

2.4.2. Very Long Baseline Array Data

The relatively low redshift and strong radio emission of the transient source made it an ideal candidate for Very Long Baseline Array (VLBA) observations. On September 30.23

¹The VLA is operated by the National Radio Astronomy Observatory, a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.

UT ($\Delta t \approx 27$ days) we observed the radio transient for a total duration of 6 hours at 8.5 GHz. Using sources J2253+1608 and J2148+0657 we were able to flux calibrate the field and we phase referenced against source J2256-2011 at a distance of < 2 degrees. Data were reduced and processed using standard VLBA packages within the Astronomical Image Processing System (AIPS). We detected the radio transient with a flux of 0.89 ± 0.17 mJy at a position coincident with the VLA and optical observations at a location of $\alpha(\text{J2000}) = 22^{\text{h}}48^{\text{m}}42.33912^{\text{s}} \pm 0.00003$, $\delta(\text{J2000}) = -20^{\circ}46'08.945'' \pm 0.0005$. This is our most accurate position measurement for the transient object. The source is unresolved within our VLBA beam size of 1.93×1.73 mas. Furthermore, the consistency between the flux measured with VLBA and low resolution VLA observations rules out the presence of diffuse components (e.g. jets).

3. The afterglow of XRF 020903

The large error box and the proximity of the optical transient to G2 and G3 delayed rapid identification of the transient (Price, Schmidt & Axelrod 2002; Pavlenko, Rumyantsev & Pozanenko 2002; Uemura *et al.* 2002; Fruchter *et al.* 2002). As a result there was little optical followup of the transient at early times (see Table 1). At later times, the transient is rapidly dominated by the emission from G1. An additional complication was introduced by Gal-Yam (2002) who, based on archival photographic plates from 1954 and 1977, proposed that G1 hosted a variable active galactic nucleus (AGN).

In contrast to the above discussion, the extensive radio light curve (Figure 5) provides strong evidence that the transient is the afterglow of XRF 020903. The radio light curve is similar to the afterglow of GRBs (Frail *et al.* 2003). At 4.9 GHz, the source was observed to rise to a peak flux at $\Delta t \approx 29$ days and subsequently decay with a characteristic index of $\alpha \approx -1.1$. A steeper decline of $F_{\nu} \propto t^{-1.5}$ was observed at 8.5 GHz where the peak flux precedes the first observational epoch. We note that the dynamic range of the radio afterglow emission clearly distinguishes the source from a radio bright AGN.

The afterglow interpretation is consistent with the optical spectroscopic observations of G1, namely the absence of broad lines or features typical of AGN, as well as the absence of any jet structure in the VLBA images of the radio transient. We proceed accepting the notion that the optical/radio transient is the afterglow of XRF 020903.

4. Energetics

At a redshift of $z = 0.251$, the X-ray fluence implies an isotropic equivalent energy $E_{\text{iso}} \approx 1.1 \times 10^{49}$ erg. This value is 3 to 6 orders of magnitude lower than the isotropic energies of gamma-ray bursts (Frail *et al.* 2001). Since there is no evidence for a jet break in the afterglow observations, the data are consistent with a wide jet or a spherical explosion. This, along with the early decline of the optical flux ($F_\nu \propto t^{-1.3}$ at $\Delta t \approx 1$ d; Figure 2) rules out the possibility that the inferred low energy is due to a viewing angle significantly away from the jet axis. In such a scenario, the optical flux would rise until the edge of the jet enters the observer’s line of sight, peaking at $\Delta t \geq t_{\text{jet}}$, where t_{jet} is the observed time of the jet break (e.g. Granot *et al.* 2002).

Figure 6 shows that although the energy in the prompt emission of XRF 020903 is significantly lower than that observed for typical GRBs, the peak luminosity of the radio afterglow is comparable to that found in GRB afterglows. This indicates that XRF 020903 has a similar kinetic energy to GRB afterglows. To study this in more detail we used standard broadband afterglow models with spherical and collimated ejecta expanding into circumburst media with uniform density and wind density profile, $\rho \propto r^{-2}$ (e.g. Berger *et al.* 2000). We find that independent of the assumed model, the total kinetic energy is $E \sim 4 \times 10^{50}$ erg with reasonable values for the circumburst density and energy fractions (electron and magnetic field) of $n \approx 100 \text{ cm}^{-3}$, $\epsilon_e \approx 0.6$ and $\epsilon_B \approx 0.01$, respectively. Thus we confirm the afterglow energy is similar to values found for GRB afterglows (Panaitescu & Kumar 2002; Berger, Kulkarni & Frail 2003).

Recent evidence suggests a standard total energy yield (10^{51} erg) for all GRBs (Berger *et al.* 2003b), where the total energy yield (E_{tot}) is defined as the sum of the energy in the prompt emission (E_γ) plus the mildly relativistic energy as inferred from the afterglow (E_{rad}). Clearly, for XRF 020903 the explosion energy is dominated by the mildly relativistic afterglow, while a minor fraction of energy couples to the high Lorentz factors characterizing the prompt emission.

Figure 6 also compares the radio luminosity of XRF 020903 with other spherical explosions – type Ibc supernovae. With a radio luminosity ~ 1000 times greater than typical Ibc SNe, it is clear that XRF 020903 is a significantly more energetic explosion. This suggests that despite their similar explosion geometries, XRF 020903 and type Ibc supernovae are intrinsically different – possibly due to the presense of a central engine (Berger *et al.* 2003a).

5. Conclusions

We present radio and optical observations of the afterglow of XRF 020903 – the first X-ray flash to have a detected optical afterglow and a spectroscopic distance determination. At a redshift of $z = 0.251$, this burst has set the distance scale for XRFs and confirmed the assumption that they are cosmological in origin. The host galaxy of XRF 020903 appears to be a typical star-forming galaxy similar to those of GRB host galaxies.

The isotropic energy release of the prompt (X-ray) emission of XRF 020903 is at least two orders of magnitude smaller than those of GRBs. However, from our broadband modeling of the afterglow we determine that the total kinetic energy is about 10^{50} erg, not dissimilar to those inferred for GRBs (Panaiteanu & Kumar 2002; Berger, Kulkarni & Frail 2003). In comparison with a larger sample of cosmic explosions, XRF 020903 is a clear example where less energy is coupled to high Lorentz factors. This source highlights the diversity in high energy transients and underscores the importance of studying spherical explosions.

We thank J. Ulvestad for his help with scheduling the VLBA observation. MH acknowledges support for this work provided by NASA through Hubble Fellowship grant HST-HF-01139.01-A awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS 5-26555. JPH and NM acknowledge support from NSF grant AST-0206051. AMS is supported by an NSF graduate research fellowship. GRB research at Caltech is supported by NASA and NSF.

Fig. 1.— The field of XRF 020903 was observed with the Palomar 200 inch telescope equipped with the Large Field Camera on 2002 September 4.32 and September 10.30 UT. Image subtraction techniques revealed one variable object within the HETE-2 error-box lying ~ 4 arcsec NW of a bright elliptical galaxy (G2). The residual image clearly indicates a transient stellar source which decreased in brightness by 1.4 magnitudes between the two epochs.

Fig. 2.— Optical (R band) lightcurve for the transient source. Data were obtained from the Palomar 200 inch and MDM 1.3 meter telescopes. The solid line is our best fit to the broadband data, including the afterglow component with a temporal decay of $\alpha \approx -1.3$ (dashed line) and the host galaxy (G1) contribution of $R \sim 20.8$ mag. The early decline rules out the possibility that the viewing angle is significantly away from the jet axis (see Granot *et al.* 2002).

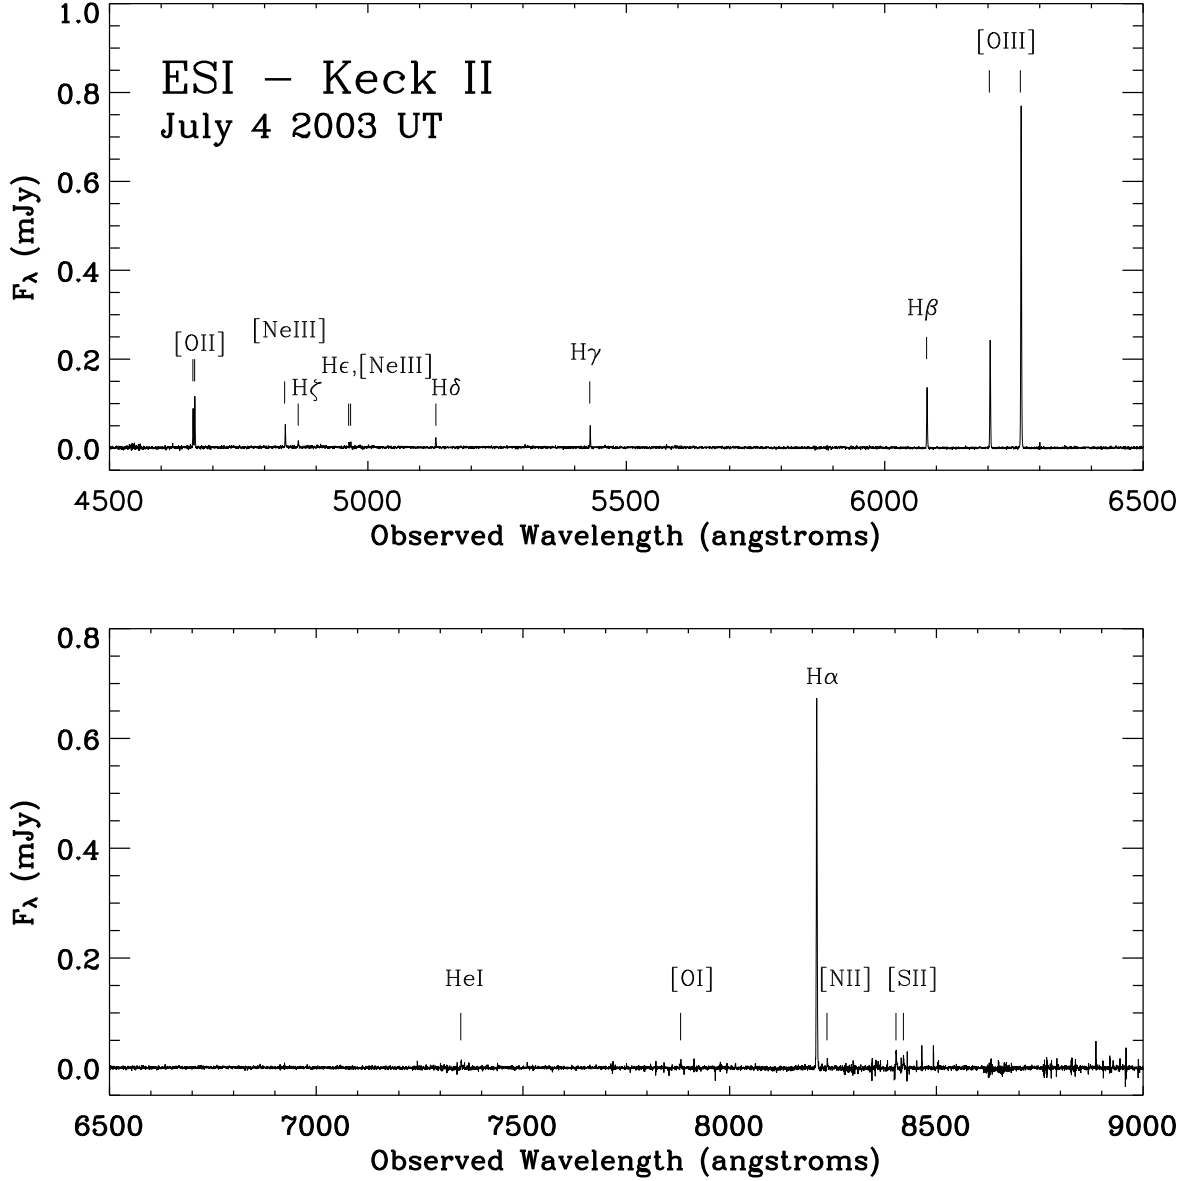

Fig. 3.— On 2003 July 4 UT we obtained spectroscopic observations of the putative host galaxy (G1) underlying the optical transient source associated with XRF 020903. Data were taken with the Echelle Spectroscopic Imager (ESI) mounted on the Keck II telescope. The source is shown to be an active star-forming galaxy at $z=0.251$ with a rich set of narrow bright emission lines.

Fig. 4.— The transient discovered within the error-box of XRF 020903 was observed with the Hubble Space Telescope (HST) using the Advanced Camera for Surveys (ACS) on 2002 December 3 UT. The HST image reveals a complicated galaxy morphology for G1, suggesting a system of at least four interacting galaxies. The location of the optical transient is noted on the $7 \times 7''$ HST cutout with a circle which represents a 2σ positional uncertainty of $0.12''$. Nearby galaxies G2 and G3 are labeled accordingly on the HST image. The optical transient appears to overlap with the SW component of the G1 complex.

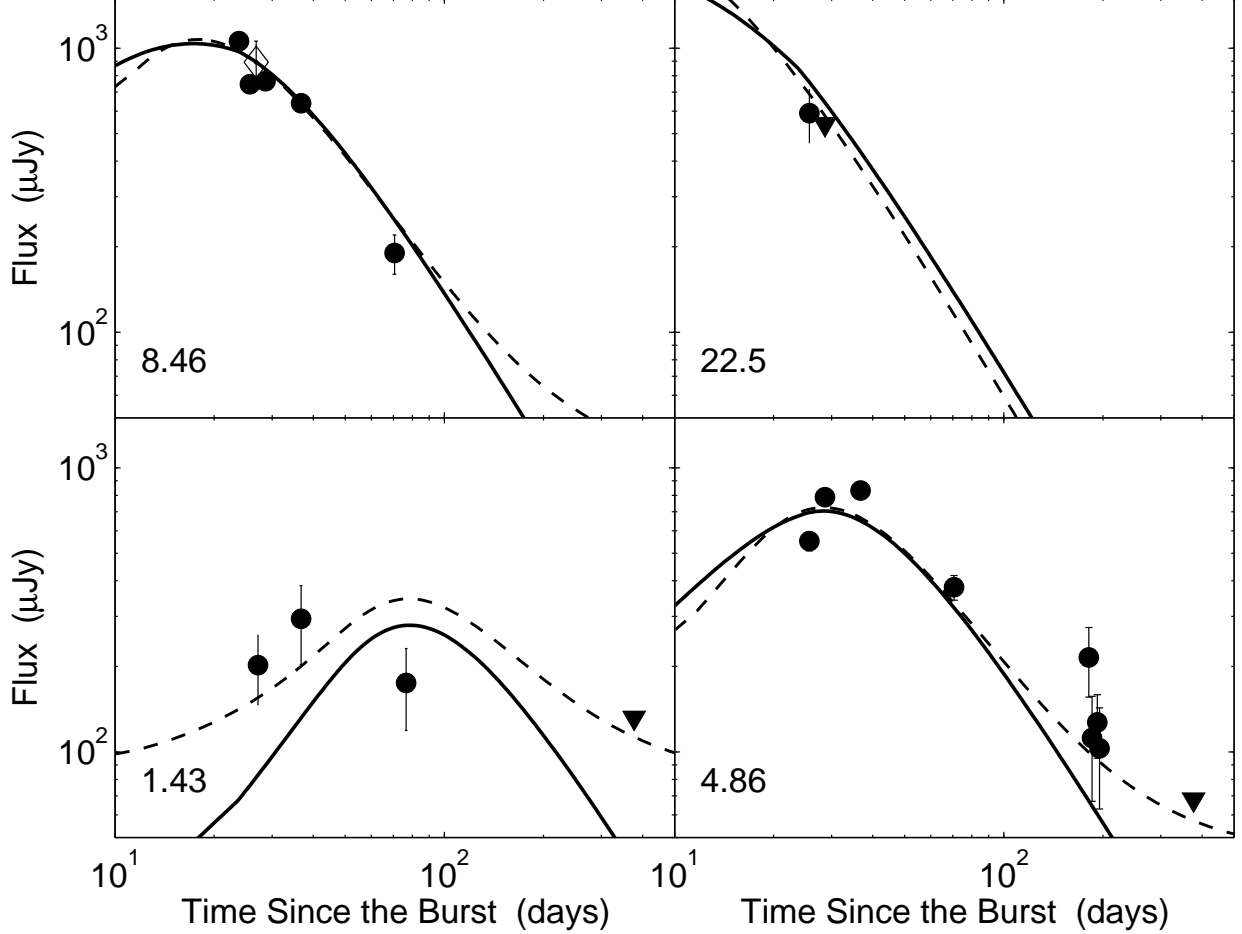

Fig. 5.— We observed the field of XRF 020903 with the Very Large Array over the period $\Delta t \approx 25 - 370$ days. A bright radio counterpart was detected at a position coincident with the optical transient. We continued monitoring the source with the VLA over the next ≈ 300 days at frequencies of 1.5, 4.9, 8.5 and 22.5 GHz. Assuming the transient source is the radio afterglow component associated with XRF 020903, we overplot the best fit broadband model (solid line) which predicts a total kinetic energy of 4×10^{50} erg in the afterglow. Allowing for a host galaxy emission component, we find a better fit assuming a host galaxy flux of $F_{1.4\text{GHz}} \approx 80 \mu\text{Jy}$ (dashed line). The implied star-formation rate from the host is $5 M_{\odot}\text{yr}^{-1}$ following the conversion from Yun & Carilli (2002). The 8.5 GHz data point marked by the open diamond symbol denotes the VLBA observation of the unresolved transient source (beam size= 1.93×1.73 mas).

Fig. 6.— The histogram above compares the peak radio luminosity for various cosmic explosions, including type Ib/c supernovae (spherical ejecta geometry) as well as typical long-duration GRBs (collimated ejecta geometry). Although the energy in the prompt emission of XRF 020903 is $10^2 - 10^3$ times lower than that observed for typical GRBs, the total kinetic energy in the afterglow of XRF 020903 is comparable to that found in typical GRBs afterglows. In comparison with a larger sample of cosmic explosions, XRF 020903 is a clear example where there is less energy coupled to high Lorentz factors.
